This paper proposes a non-model-based approach to iterative learning control (ILC) via extremum seeking. Single-input–single-output discrete-time nonlinear systems are considered, where the objective is to recursively construct an input such that the corresponding system output tracks a prescribed reference trajectory as closely as possible on finite horizon. The problem is formulated in terms of extremum seeking control, which is amenable to a range of local and global optimisation methods. Contrary to the existing ILC literature, the formulation allows the initial condition of each iteration to be incorporated as an optimisation variable to improve tracking. Sufficient conditions for convergence to the reference trajectory are provided. The main feature of this approach is that it does not rely on knowledge about the system's model to perform iterative learning control, in contrast to most results in the literature.

1. Introduction

Iterative learning control (ILC) is a learning based method for tracking a prescribed trajectory. It carries out the same task multiple times with respect to recursively updated control inputs while improving the tracking performance by learning from previous executions (Moore, 1993; Moore, Dahleh, & Bhattacharyya, 1992; Xu & Tan, 2003). ILC is known to achieve good performance in the presence of repeating disturbances and certain model uncertainty due to its iteratively learning feature. Practically, ILC has been applied to a wide range of engineering applications, including robotics (Messner, Horowitz, Kao, & Boals, 1991), induction motors (Saab, 2004), rolling mills (Carimella & Srinivasan, 1998), stroke rehabilitation (Freeman, Rogers, Burridge, Hughes, & Meadmore, 2015; Freeman, Rogers, Hughes, Burridge, & Meadmore, 2012), and aluminum extruders (Pandit & Buchheit, 1999); see Ahn, Chen, and Moore (2007) for a classification of the ILC literature. It is also useful within the context of motion planning (Srinivasan & Ruina, 2006). Bristow, Tharayil, and Alleyne (2006) contains an excellent survey of a particular ILC algorithm by Moore (1993), where several topics in analysis (e.g. performance, transients, robustness) and design methods (e.g. plant inversion, quadratically optimal) are covered.

This paper proposes an extremum-seeking based framework within which to perform iterative learning control of discrete-time single-input–single-output time-varying nonlinear systems on finite horizon. It is noted here that multi-input–multi-output systems are addressable with the same approach. A key feature of extremum seeking is its ability to locate an optimum with respect to some measure without assuming knowledge about the underlying models governing the dynamics of the nonlinear systems (Ariyur & Krstić, 2003; Zhang & Ordóñez, 2011). Such knowledge may be unavailable due to the difficulty associated with modelling of complicated nonlinear systems. Extremum seeking has found applications in a wide array of problems, including biochemical reactors (Guay, Dochain, & Perrier, 2003; Wang, Krstić, & Bastin, 1999), gas-turbine combustors (Moase, Manzie, & Brear, 2010), power electronics (Scheinker, Bland, Krstić, & Audia, 2014), multi-agent source seeking (Khong, Tan, Manzie, & Nešić, 2014), and finite-horizon optimal control (Frihauf, Krstić, & Başar, 2013). Within the context of ILC, extremum seeking has been applied to pulse shaping in a double-pass laser amplifier (Ren, Frihauf, Rafac, & Krstić, 2012).

In this paper, we propose a unifying framework in which to apply optimisation-based extremum seeking algorithms to ILC in the spirit of Khong, Nešić, Tan, and Manzie (2013) and...
Nešić, Tan, Moase, and Manzie (2010). In particular, the proposed framework is shown to be amenable to a broad range of local and global optimisation methods (Khong, Nešić, Manzie, & Tan, 2013; Pintér, 1996; Teel & Popović, 2001). This allows complexity of implementation and convergence speed of the algorithms to be taken into account in the control design stage. For instance, if large variations in the control input is undesirable but convergence to local optima is tolerable, local optimisation methods may be selected. Furthermore, Newton-based methods can be employed if a quadratic convergence rate is solicited. In the proposed framework, the cost function is defined as the distance between the system output and the reference trajectory. For local optimisation methods, ultimately bounded asymptotic stability of local minima is demonstrated. In the case of global optimisation, it is shown that the proposed ILC converges to a global minimum.

Several optimisation-based ILC methods can be found in the literature, but the vast majority of them rely on knowledge on the models. For instance, the updating control laws as well as convergence of the ILC methods in Gunnarsson and Norrlöf (2001) and Owens and Hätönen (2005) depend on the precise knowledge of the nominal model. Owens, Hatonen, and Daley (2009) proposes a robust monotone gradient-based scheme for ILC of linear time-invariant (LTI) systems, where the multiplicative modelling uncertainty is assumed to be bounded. The robustness analysis therein redesigns that performed in Bristow et al. (2006). Schoellig, Mueller, and D’Andrea (2012) considers the case where an LTI model is subject to noisy disturbances and proposes a combined model-based Kalman filter and convex optimisation approach to ILC. Mishra, Topcu, and Tomizuka (2011) proposes a primal barrier method to ILC of LTI systems contingent on the availability of knowledge about the gradient and Hessian of the quadratic cost function, which in turn is dependent on the models.

While the standard ILC literature considers learning controllers for systems that perform the same operation repetitively under the same initial conditions, we depart from such a setting and incorporate the initial conditions as parts of the optimisation variables, so that they may vary from one iteration to the next for improved tracking. Indeed, the former is subsumed by the latter by setting the initial conditions to be constant across all iterations. The formulation in this paper differs from that of repetitive control (Longman, 2000) and repetitive learning control (Sun, Ge, & Mareels, 2006), where the initial conditions of the current iteration are set to be the final conditions of the previous trial. It is also noteworthy that the proposed extremum seeking based ILC, which updates the control input signal, differs from iterative feedback tuning (Hjalmarsson, Gevers, Gunnarsson, & Lequin, 1998), where non-model based optimisation methods are exploited to iteratively tune controller’s parameters in order to achieve tracking of an output trajectory given a fixed reference input.

The paper has the following structure. A formal definition of ILC and the class of nonlinear systems considered in this paper are stated in the next section. In Section 3, ILC is formulated in terms of an extremum seeking problem. Subsequently, local and global optimisation based extremum seeking approaches are discussed in Sections 4 and 5 respectively. Section 6 contains simulation examples illustrating the main results. Finally, some concluding remarks are provided in Section 7.

2. Iterative learning control

The problem of iterative learning control (ILC) is formulated in this section. The special case where the plant is linear time-invariant (LTI) and a commonly used ILC method are reviewed.

2.1. Nonlinear plants

Consider the following dynamical discrete-time time-varying nonlinear state-space system defined over a finite time interval/horizon $k = 0, 1, \ldots, T$:

$$
x(k + 1) = f(x(k), u(k), k)
\quad x(0) = \bar{x};
\quad y(k) = h(x(k), u(k), k),
$$

where $f : \mathbb{R}^n \times \mathbb{R} \times T \rightarrow \mathbb{R}^n$ and $h : \mathbb{R}^n \times \mathbb{R} \times T \rightarrow \mathbb{R}$ are locally Lipschitz functions in each argument and $T := \{0, 1, \ldots, T\}$. Repeated disturbances that are present on both the state-update differential and state-to-output algebraic equations are accounted for by $f$ and $h$ being functions of the time unit $k$. The corresponding input–output operator for system (1) is denoted by $\Sigma$, whereby $y = \Sigma (x, u)$. Also, given a $z : T \rightarrow \mathbb{R}$, define the $l^2$ norm by

$$
\|z\|_2 := \sqrt{\sum_{t=0}^{T} z(t)^2}.
$$

With a slight abuse of notation, $\|v\|_2$ is also used to denote the Euclidean norm for the vector $v \in \mathbb{R}^n$. Only discrete-time plants are considered in this paper. It is a natural formulation because ILC uses information from previous trials which needs to be stored on suitable digital media. By the same token, the dynamics of the plant are assumed to evolve along a finite horizon $[0, T]$.

Denote by $r : T \rightarrow \mathbb{R}$ the reference trajectory. The control objective is to construct a $u^*$ and an $\bar{x}^*$ such that the corresponding system output $y^* = \Sigma (\bar{x}^*, u^*)$ tracks $r$ as accurately as possible. In other words,

$$
(\bar{x}^*, u^*) := \arg \min_{u \in \Omega} \|r - \Sigma (\bar{x}, u)\|_2,
$$

where $\Omega$ is an appropriate compact subset of $(u : T \rightarrow \mathbb{R})$ and $\Omega$ a compact subset of $\mathbb{R}^n$. In general, any $\ell^p$-norm may be employable when defining the distance above. Note that a reference $r$ may not be realisable by the system, i.e. there exist no $\bar{x}^*$ and $u^*$ such that $\Sigma (\bar{x}^*, u^*) = r$. In this case, the achievable minimum of the optimisation problem above is nonzero. When $\Sigma$ is an LTI operator, realizability of references may be studied using the notions of controllability and observability. Characterising this when $\Sigma$ is nonlinear is a lot harder, and may require knowledge about the solutions to (1).

When $f$ and $h$ are known precisely, a brute-force optimisation over $\bar{x}, u(1), \ldots, u(T)$ can be used to generate a $y^*$ such that the error $e(k) := r(k) - y^*(k)$ is minimised. Alternatively, should this prove to be an infeasible approach, by introducing an additional iteration-time domain $f$, several model-based ILC algorithms in the literature (Moore, 1993; Xu & Tan, 2003) can be used to iteratively design $u_s$ based on previous trials’ outputs $y_i = \Sigma (\bar{x}, u_i)$ for $i < j$ such that $u_j \rightarrow u^*$ in the $\ell^2$-norm for a fixed $\bar{x}$ across all iterations. By tuning the parameters of the ILC algorithms appropriately, the desired transient properties, such as monotone convergence, may be achieved.

Control design in ILC can be specified in the following form. If $\bar{x}_i$ is the initial condition and $u_i$ is the input applied to the plant at trial $j = 0, 1, \ldots$ and $e_j := r - y_j = r - \Sigma (\bar{x}_j, u_j)$ is the resulting tracking error, the control design involves constructing an iteratively updated control law expressed as a functional relationship typified by the equation

$$
\begin{align*}
\bar{x}_{j+1} &= g_j (e_j, \ldots, e_{j-s}, u_j, \ldots, u_{j-s}, \bar{x}_j, \ldots, \bar{x}_{j-s}), \\
u_{j+1} &= g_j (e_j, \ldots, e_{j-s}, u_j, \ldots, u_{j-s}, \bar{x}_j, \ldots, \bar{x}_{j-s}),
\end{align*}
$$

where $s, t \leq j$. Ideally, the control law should have the property that $\lim_{j \rightarrow \infty} u_j = u^*$ and $\lim_{j \rightarrow \infty} \bar{x}_j = \bar{x}^*$, or equivalently, $e_{\infty} := \lim_{j \rightarrow \infty} e_j = 0$. A looser requirement on this is that there exists some small $\epsilon > 0$ such that $\|u_{j-s} - u^*\| < \epsilon$ and...
3. An extremum seeking approach to iterative learning control

In this section, an extremum seeking approach to ILC of nonlinear system (1) without assuming knowledge on the model is proposed. Unlike the LTI ILC scheme in Bristow et al. (2006), Moore (1993) and Moore et al. (1992), the approach builds upon well-studied optimisation methods (Boyd & Vandenberghe, 2004; Jones, Pertunnen, & Stuckman, 1993), in which the significance of the convergence properties is better understood. This section sets up the framework in which to apply local and global optimisation methods to ILC in subsequent sections.

The object under study is the nonlinear time-varying plant \( \Sigma \) given in (1). For all iterations \( j = 0, 1, \ldots \), the system output \( y_j : T \rightarrow \mathbb{R} \) is related to the system input \( u_j : T \rightarrow \mathbb{R} \) and initial condition \( x_j \in \mathbb{R}^n \) through the state \( x_j : T \rightarrow \mathbb{R}^n \) by

\[
x_j(k + 1) = f(x_j(k), u_j(k), k), \quad x_j(0) = \bar{x}_j;
\]

\[
y_j(k) = h(x_j(k), u_j(k), k).
\]

The formulation above can be transformed into a problem of static optimisation, as shown below. Denote by \( \mathcal{U} \) the set of functions \( u : T \rightarrow \mathbb{R} \). Given a vector \( v \in \mathbb{R}^{n+1} \), define the demultiplexer \( D : \mathbb{R}^{n+1} \times \mathcal{U} \rightarrow \mathbb{R}^n \times \mathcal{U} \) by

\[
D(v) = (w, z)
\]

\[
w = [v_1, \ldots, v_n]^T \quad \mbox{and} \quad z(k) = v_{n+k} \quad k = 0, 1, \ldots, T.
\]

Similarly, given a \( w \in \mathbb{R}^n \) and \( z \in \mathcal{U} \), define the multiplexer \( M : \mathbb{R}^n \times \mathcal{U} \rightarrow \mathbb{R}^{n+1} \) by

\[
v = M(w, z)
\]

\[
v_i = v_{i-1}, \quad i = 1, \ldots, n
\]

\[
v_k = z(k) \quad k = n + 1, n + 2, \ldots, n + T + 1.
\]

The demultiplexer and multiplexer are useful for analytically connecting the behaviour of the plant with the optimisation method, as will be demonstrated later.

In this section, an extremum seeking approach to ILC of nonlinear system (1) without assuming knowledge on the model is proposed. Unlike the LTI ILC scheme in Bristow et al. (2006), Moore (1993) and Moore et al. (1992), the approach builds upon well-studied optimisation methods (Boyd & Vandenberghe, 2004; Jones, Pertunnen, & Stuckman, 1993), in which the significance of the convergence properties is better understood. \]

The demultiplexer and multiplexer are useful for analytically connecting the behaviour of the plant with the optimisation method, as will be demonstrated later.
Assumption 3. The optimisation method $\Gamma$, when applied to (6), satisfies the following conditions:

(i) $\Gamma$ is time-invariant. Denote by $\{\delta(t)\}_{t=0}^{\infty} \subset \Omega \subset \mathbb{R}^m$ the output sequence $\Gamma$ generates based on inputs to $\Gamma$, where $\delta(t) = Q(\theta(t))$. $\Gamma$ is causal in the sense that the output at any time $N \in \mathbb{N}$, i.e. $\delta_N$, is determined based only on $\theta_j$ and $\delta_j$ for $j = 0, 1, \ldots, N - 1$, i.e. the past probe values to $Q$ and the corresponding measurements.

(ii) Denote by $\delta(t)$ the set of all admissible output sequences of $\Gamma$ with respect to the initial point $\theta_0$. There exists a class-$\mathcal{K}$ function $\beta$ such that for any initial point $\theta_0 \in \Omega$, all outputs $\theta \in \delta(t)$ satisfy for some $\delta \geq 0$

$$\|\delta(t)(\theta_0)\|_e \leq \beta(\|\theta_0\|_e, J) + \delta \quad \forall j \geq 0. \quad (7)$$

Note that Assumption 3(ii) states that the sequence $\delta(t)$ converges asymptotically to a $\delta$-neighbourhood of $e$.

Remark 4. The set of outputs $\delta(t)$ in Assumption 3(ii) arises, for example, from modelling the optimisation algorithm with a difference inclusion involving a set-value ‘state-update’ map $F$ by $\theta^+ \in F(\theta, Q(\theta))$; see Kelley and Teel (2005). In the simplest case, $\delta(t)$ is a singleton, i.e. there is only one possible output sequence given a fixed initial condition. For example, one modelled by the difference equation $\theta^+ = F(\theta, Q(\theta))$.

Recall the demultiplexer $D$ and multiplexer $M$ defined in (3) and (4) respectively.

Theorem 5. Given a nonlinear plant $\Sigma$ in (1) and a reference trajectory $r \in \mathcal{U}$, the feedback interconnection shown in Fig. 1 with the optimisation method $\Gamma$ satisfying Assumption 3 in which $m = n + T + 1$ has the following convergence property: there exists a class-$\mathcal{L}$ function $\beta$ such that for any initial point $\theta_0 \in \Omega$ and some $\delta \geq 0$.

$$\|M(\bar{x}_j, u_j)\|_e \leq \beta(\|M(0, 0)\|_e, J) + \delta \quad \forall j \geq 0. \quad (8)$$

where $Q : \Omega \subset \mathbb{R}^m \rightarrow \mathbb{R}$ is as defined in (5), whose Jacobian is zero on $\mathcal{C} \subset \Omega$, the search domain of interests.

Proof. Note that by the setup of the feedback interconnection in Fig. 1, $M(\bar{x}_j, u_j) = D(\theta_j)$ for all $j = 0, 1, \ldots$. By applying $\Gamma$ to $Q$, it follows from Assumption 3 that there exists a class-$\mathcal{K}$ function $\beta$ such that for any initial point $\theta_0 \in \Omega$ and some $\delta \geq 0$.

$$\|\theta_j\|_e \leq \beta(\|\theta_0\|_e, J) + \delta \quad \forall j \geq 0. \quad (9)$$

This is equivalent, via the relationship $(\bar{x}_j, u_j) = D(\theta_j)$, to (8), as claimed. □

Theorem 5 contains sufficient conditions under which the iterations on $\bar{x}_j$ and $u_j$ are convergent in a $\delta$-neighbourhood of local minima of the function $Q$ defined in (5), which measures the $\ell^2$-size of the tracking error.

In the following, we detail two of the most well-known methods (Boyd & Vandenberghe, 2004; Polak, 1997) in operations research which satisfy Assumption 3. They are the (i) gradient descent method:

$$\theta_{j+1} = \theta_j - \lambda_j \nabla Q(\theta_j), \quad (10)$$

where $\lambda_j$ denotes the step size which can be computed by, say, the Armijo method (Polak, 1997, Alg. 1.3.3) and (ii) Newton’s method:

$$\theta_{j+1} = \theta_j - \nabla^2 Q(\theta_j)^{-1} \nabla Q(\theta_j), \quad (11)$$

where $\nabla Q(\cdot)$ and $\nabla^2 Q(\cdot)$ denote, respectively, the Jacobian and Hessian of $Q$. It can be readily seen that the gradient and Newton methods satisfy the time-invariance and causality Assumption 3(iii). The following result can be found in Boyd and Vandenberghe (2004) and Polak (1997).

Proposition 6. Suppose $Q : \Omega \rightarrow \mathbb{R}$ is twice Lipschitz continuously differentiable and strictly convex on $\delta \subset \Omega$, whereby there exist $M, M \in \mathbb{R}$ such that

$$MI \leq \nabla^2 Q(\theta) \leq \bar{M}I \quad \forall \theta \in \delta.$$ 

Furthermore, suppose there exists a minimiser $\theta^* \in \delta$ such that $\nabla Q(\theta^*) = 0$. Let $\{\theta_j\}_{j=0}^{\infty}$ be the sequence generated by the gradient or Newton method when applied to minimising $Q$. Then there exists a class-$\mathcal{K}$ function $\beta$ such that for any $\theta_0 \in \delta$,

$$\|\theta_j - \theta^*\|_2 \leq \beta(\|\theta_0 - \theta^*\|_2, J) \quad \forall j \geq 0. \quad (12)$$

Note that the rate of convergence for the gradient descent method is linear while that for Newton is quadratic, at least within a sufficiently small neighbourhood of the minimiser.

Proposition 6 states the convergence conditions for the gradient descent and Newton method when exact values of the Jacobian $\nabla Q(\theta)$ and Hessian $\nabla^2 Q(\theta)$ are available. In practice, they need to be estimated from several past measurements. This can be achieved by using the Euler methods, trapezoidal method, or the more sophisticated Runge–Kutta methods (Press, Teukolsky, Vetterling, & Flannery, 2007); see Fig. 2.

To be more specific, let the initial output of the optimisation method be $\theta_0 = \bar{\theta}_0$. As determined by the derivative estimator, the following length-$p$ sequence of step commands $\{\theta_i\}_{i=0}^p$ can be used to probe $Q$ along the desired directions:

$$(\bar{\theta}_0 + d_1(\bar{\theta}_0), \ldots, \bar{\theta}_0 + d_p(\bar{\theta}_0)), \quad (13)$$

where $d_i : \Omega \rightarrow \mathbb{R}^m$, $i = 1, \ldots, p$ denote the dither signals. The corresponding outputs of $Q$ are then collected by the derivative estimator to numerically approximate the Jacobian $Q(\theta_0)$. Exploiting this information, the optimisation algorithm can then update its next probing point $\bar{x}_{i+1}$, and the series of steps described above repeat to generate $\{\theta_j\}_{j=0}^{p-1}$.

Suppose the use of the derivative estimates (instead of their precise values) in Fig. 2 introduces a bounded additive error term in the update of the gradient and Newton methods:

$$\theta_{j+1} = \theta_j - \lambda_j \nabla Q(\theta_j) + e_1(k, \theta_j) \quad \text{and} \quad \theta_{j+1} = \theta_j - \nabla^2 Q(\theta_j)^{-1} \nabla Q(\theta_j) + e_2(k, \theta_j), \quad (14)$$

where

$$\|e_1(k, \theta_j)\|_2 \leq l_1 + q \alpha(\|\theta_j\|_e) \quad \text{and} \quad \|e_2(k, \theta_j)\|_2 \leq l_2 + q \alpha(\|\theta_j\|_e), \quad (15)$$

for some $l_1, l_2, q_1, q_2 \geq 0$. It follows from the non-vanishing perturbation results for discrete-time systems in Cruz-Hernández, Alvarez-Gallegos, and Castro-Linares (1999) that for sufficiently small $l$ and $q$, the gradient/Newton-based extremum seeking controller in Fig. 2 satisfies the ultimately bounded asymptotic stability Assumption 3(iii). In particular, there exist a class-$\mathcal{K}$ function $\alpha$ and a class-$\mathcal{K}$ function $\beta$ such that

$$\|\theta_j\|_e \leq \beta(\|\theta_0\|_e, J) + \alpha(l) \quad \forall j = 0, 1, \ldots.$$ 

Assumption 7. There exists an $\alpha_0 \in \mathcal{K}$ and $c > 0$ such that the dither signals in (11) satisfy for each $i = 1, \ldots, p$,

$$\|d_i(\theta_j)\|_2 \leq \alpha_0(\|\theta_j\|_e) + c.$$
When Assumption 7 holds with $c = 0$, it follows that the step size used in estimating the derivatives converges to zero as $\theta_i$ tends to the minimising set $C$. This implies by the definition of differentiation that the magnitudes of the error terms $e_1$ and $e_2$ in (13) tend to zero as $k \to \infty$, i.e. $l_1 = l_2 = 0$. In other words, the perturbations are vanishing and the extremum seeking controller is asymptotically stable as in Assumption 3(ii) with $\delta = 0$ (Cruz-Hernández et al., 1999).

**Remark 8.** When the plant $\Sigma$ in Theorem 5 is LTI, the resulting $Q$ in (5) is convex. It follows that either the gradient descent or Newton methods would result in convergence to a neighbourhood of a global minimum of $Q$. On the contrary, if $\Sigma$ is nonlinear, convergence to a neighbourhood of a local minimum can be achieved.

Besides the gradient descent and Newton methods detailed above, other local optimisation methods satisfying Assumption 3 include the following difference inclusion form (Teel & Popović, 2001):

$$\theta_{i+1} \in F(\theta_i, G(\theta_i)), \quad (14)$$

where $F$ is an upper semi-continuous set-valued map (the update $\theta^+$ can be any element of the set) and $G$ is a function that carries information regarding the estimate of the gradient of $Q$ around $\theta$. In particular, $F$ maps from $\mathbb{R}^n \times \mathbb{R}^p$ to subsets of $\mathbb{R}^m$,

$$G(\theta_i) := \begin{bmatrix} Q(\theta_i + d_1(\theta_i)) \\ \vdots \\ Q(\theta_i + d_p(\theta_i)) \end{bmatrix},$$

and $d_i : \Omega \rightarrow \mathbb{R}$, $i = 1, \ldots, p$ are either/perturbation functions. See Teel (2000) for a class of Lyapunov-based non-smooth optimisation algorithms of the form described above which employ the notion of Clarke generalised gradient.

## 5. Global optimisation

In the case where large variations in the initial condition and control input can be tolerated from iteration to iteration, sampling-based global optimisation methods which do not exploit information about gradients of the cost function can be employed to locate global minima in the presence of local ones in ILC. Bounds on initial conditions and input saturation constraints are naturally accommodated by these methods. This section adapts such methods for ILC within the framework of extremum seeking control described in Section 3.

Consider the following bound-constrained optimisation problem:

$$z^* := \min_{\theta \in \Omega} Q(\theta), \quad (15)$$

where

$$\Omega := \{ \theta \in \mathbb{R}^m \mid \theta_i \in [a_i, b_i] \subset \mathbb{R}, i = 1, 2, \ldots, m \}. \quad (16)$$

Assume that $Q : \Omega \subset \mathbb{R}^m \rightarrow \mathbb{R}$ is a globally Lipschitz continuous function (Khalil, 2002), i.e. there exists a known $L > 0$ such that

$$|Q(\theta) - Q(\theta')| \leq L|\theta - \theta'|_2$$

for all $\theta, \theta' \in \Omega$. Note that $Q$ possesses a global minimum by the extreme value theorem (Rudin, 1976, Thm. 4.16) since it is (Lipschitz) continuous on a compact domain $\Omega$. The compactness is motivated by the ubiquity of control input saturation constraints in physical systems (Khalil, 2002). It is assumed that $Q$ achieves its global minimum on a nonempty set $C \subset \Omega$.

A global optimisation method $\Gamma$ may generate its update according to

$$\theta_{j+1} = \Gamma(\theta_j, \ldots, \theta_{j-1}, z_j, \ldots, z_{j-k}),$$

where $z_j = Q(\theta_j)$. Define

$$\hat{z}_k := \min_{i=0, 1, \ldots, k} z_i.$$

In what follows we consider global optimisation algorithms that satisfy the next assumption.

**Assumption 9.** The global optimisation algorithm $\Gamma$, when applied to optimisation (15), has the convergence property that a subsequence of $\{\theta_i\}^{\infty}_{i=0}$ converges to $\hat{z}^*$, which implies that $\hat{z}_k \rightarrow \hat{z}^*$.

**Theorem 10.** Given a nonlinear plant $\Sigma$ in (1) and a reference trajectory $r \in U$, the feedback interconnection shown in Fig. 1 with the optimisation method $\Gamma$ satisfying Assumption 9 in which $m = n + 1 + \Gamma$ has the following convergence property: $\{M(x, u_i)\}^{\infty}_{i=0}$ has a subsequence which converges to $C$, where $Q : \Omega \subset \mathbb{R}^m \rightarrow \mathbb{R}$ as defined in (5) achieves its global minimum on a nonempty set $\bar{C} \subset \Omega$ and $\bar{C}$ is as in (16) for some $d_i, b_i \in \mathbb{R}$, $i = 1, \ldots, m$.

**Proof.** It can be seen from the feedback interconnection in Fig. 1 that $(\hat{x}_i, u_i) = D(\theta_i)$ for all $i = 0, 1, \ldots, 1$. By applying $\Gamma$ to $Q$, it follows from Assumption 9 that a subsequence of $\{\theta_i\}^{\infty}_{i=0}$ converges to $C$. This is equivalent, via the relationship $(\hat{x}_i, u_i) = D(\theta_i)$, to $\{M(\hat{x}_i, u_i)\}^{\infty}_{i=0}$ having a subsequence which converges to $C$. \hfill \Box

While a wide range of global optimisation algorithms satisfying Assumption 9 are available in the literature (Pintér, 1996; Strongin & Sergeyev, 2000), we describe in the following a particular one called the DIRECT (Dividing Rectangles) optimisation method (Jones et al., 1993) to be used in the simulation example later.

### 5.1. DIRECT optimisation algorithm

Here, a brief review of the DIRECT optimisation method (Jones et al., 1993) is given. DIRECT is a deterministic sampling method which solves (15). The only assumption that DIRECT makes is the Lipschitz continuity of $Q$. DIRECT does not require knowledge of the function $Q$ or the Lipschitz constant. It also makes no attempt at estimating derivatives of $Q$.

**Algorithm 1.** The DIRECT algorithm (Jones et al., 1993).

Given: A Lipschitz function $Q : \Omega \subset \mathbb{R}^m \rightarrow \mathbb{R}$.

Notation: $q$ denotes the iteration number of DIRECT and $k$ the total number of samples. Input samples taken by DIRECT are denoted $\theta_i \in \Omega, i = 0, 1, \ldots, k-1$ and the corresponding outputs $z_i := Q(\theta_i)$.

(i) Initialise $q := 1$ and $k := 0$.
(ii) Evaluate $Q(\theta_0)$, where $\theta_0 \in \mathbb{R}^m$ denotes the centre point of $\Omega$. Set $z_0 := Q(\theta_0)$ and increment $k$, i.e. $k^* := k + 1$.
(iii) Identify the set of indices of potentially optimal hyper-rectangles $S$, i.e. all $j \in \{0, \ldots, k-1\}$ for which there exists a positive $L_j \in \mathbb{R}$ such that

$$Q(\theta_j) - L_d \leq Q(\theta_j) - L_d, \quad \forall i = 0, \ldots, k-1$$

$$Q(\theta_j) - L_d \leq z_j - z_k \leq |z_j| \quad \text{for some } \epsilon > 0, \quad (17)$$

where $d_i$ denotes the distance from the centre point to the vertices of the $i$th hyper-rectangle. As noted in Jones et al. (1993), the set of potentially optimal hyper-rectangles can be found using Graham’s scan (Graham, 1972), which is an efficient algorithm for determining the convex hull of a finite set.
Proposition 11

whereby Theorem 10 holds with DIRECT being the optimisation method, which exploits it to expedite the search (Jones et al., 1993). Indeed, once DIRECT locates the basin of convergence of (17) for subdivision, it is well-balanced between local and global optimisation. Indeed, once DIRECT identifies all potentially optimal hyper-rectangles via a numerical implementation of the algorithm using MATLAB. The following demonstrates that the DIRECT algorithm satisfies Assumption 9, whereby Theorem 10 holds with DIRECT being the optimisation method.

Proposition 11 (Jones et al., 1993). As the number of iterations approaches infinity, the points sampled by DIRECT form a dense subset of $\Omega$. Since $Q$ is Lipschitz continuous, the estimate by DIRECT converges to $z^*$ in (15). Mathematically, it holds that

$$\lim_{q \to \infty} \hat{z}_q = z^* = \min_{\theta \in \Omega} Q(\theta).$$

The denseness in domain-sampling property of DIRECT mentioned in the proposition above is of critical importance in the proof of its convergence. It holds by the way the algorithm is set up, which subdivides all potentially optimal rectangles in the search space iteratively.

6. Illustrative examples

Consider the following forced pendulum equation modified from Khalil (2002, Example 4.4):

$$\dot{x}_1 = x_2$$
$$\dot{x}_2 = -\sin(x_1) - 0.2x_2 + u$$
$$y = x_1.$$
with the optimisation method being the DIRECT Algorithm 1.

6.2. DIRECT method

The same ILC scheme in Fig. 1 is applied to the plant (19), but with the optimisation method being the DIRECT Algorithm 1. Suppose that each coordinate of the initial condition and input lies within the compact interval \([-15, 15]\), i.e. \(a_i = -15\) and \(b_i = 15\) for \(i = 1, \ldots, 13\) in (16).

After 34 iterations of the DIRECT algorithm and 15,293 runs of the plant, the final \(L^2\) tracking error achieved is 3.79. Fig. 6 illustrates the tracking error with respect to the number of runs of the plant. The resulting initial condition is \([1.11, 5.56]\). Fig. 7 shows the resulting input and the corresponding output.

7. Conclusions

An extremum seeking based framework has been proposed for iterative learning control of discrete-time nonlinear time-varying systems. It is demonstrated that the framework accommodates both local and global optimisation algorithms. Simulation examples are provided to illustrate the results. Future research directions may involve investigating iterative learning under noisy measurements and stochastic optimisation methods.
